ABSTRACT

Objective: The present study aimed to evaluate the effectiveness and reliability of titanium-platelet-rich fibrin (T-PRF) autograft implantation in patients who underwent this treatment method.

Methods: Our study included patients who underwent titanium-platelet-rich membrane autograft implantation at our clinic for the management of primary pterygium. Demographic characteristics of patients, size of the pterygium as determined during pre- and postoperative biomicroscopic examinations, presence of granulation tissue, recurrence, corneal, and other complications, condition of the implanted graft, and conjunctival epithelialization were evaluated. The absence of recurrence was considered as a criterion of success.

Results: Twelve eyes belonging to total 12 patients (men, 5 and women, 7) with a mean age of 52.1 ± 12.6 (range, 30–75) years and mean follow-up period of 2.91 ± 1.37 (range, 1–5) months were included in the study. The follow-up period of total 8 cases exceeded 3 months. Recurrence was observed in 2 (16.6%) cases.

Conclusion: Because no complications were observed in our study, this new surgical technique was considered reliable. Based on our preliminary reports, T-PRF autograft technique can be used as an alternative to other surgical techniques.

Keywords: Titanium-platelet-rich fibrin, autograft, pterygium

INTRODUCTION

Pterygium is a degenerative, proliferative ocular surface disease characterized by fibrovascular extension of the conjunctiva over the cornea. It progresses slowly and courses with periods of inflammatory episodes and inactive periods. Clinically, the prevalence of pterygium ranged between 4% and 31% (1–4). The etiopathogenesis of pterygium has not been completely elucidated (5, 6).

The pathology of pterygium is characterized by conjunctivalization, chronic inflammation, cellular proliferation, remodeling of the connective tissue, and neovascularization. Several molecules, including fibroblast growth factor, platelet-derived growth factor (PDGF), transforming growth factor (TGF), tumor necrosis factor (TNF), cytokines, and matrix metalloproteinases, play roles in this active and invasive process (7, 8).

The main treatment for pterygium is surgery, and the basic objective is the prevention of recurrence. However, the most effective technique has not been precisely determined (9, 10). The oldest method used for pterygium surgery is the bare sclera technique. Implantation of conjunctival autograft, limbal conjunctival autograft, and amniotic membrane has been applied as surgical treatment. Combination treatments with chemotherapy, anti-vascular endothelial growth factor inhibitor (VEGFi), and radiotherapy have been integrated with these techniques to increase the success rates of surgical treatments (11).

Choukroun developed a platelet-rich fibrin (PRF) that contained intensive amounts of leukocytes and platelets (12). In this method, blood samples are placed in a glass tube and are centrifuged without adding any anticoagulant or cattle thrombin (13, 14). Some studies noted that blood prepared in a glass tube is activated with silica and that its fibrin content may have some side effects (15). Tunalı et al. (16) eliminated the adverse effects of silica by preparing L-PRF with titanium (titanium-platelet-rich fibrin, T-PRF). In histomorphometric analyses, it has been demonstrated that T-PRF has a tight fibrin network, and in vivo studies have displayed longer resorption times than Choukroun's autogenous fibrin. Ustaoglu et al. (17) demonstrated the favorable effects of the T-PRF membrane on the healing of palatal mucosa wounds.

In a study performed by Can et al. (18) on rabbits, the favorable effects of PRF, which they had prepared in a glass tube on conjunctival healing had been demonstrated. The previous study suggested that this autograft can be used in the surgical treatment of pterygium. In our literature review, we could not find any study performed with T-PRF autograft in the treatment of pterygium surgery. Therefore, the present study aimed to determine the effectiveness and success of using T-PRF in the surgical treatment of pterygium.

obtained. Routine ophthalmologic examinations of the patients were performed and the patients were informed about the operation.

All cases operated between December 2016 and May 2017 using T-PRF autograft technique were included in the study. Pterygia exceeding the limbus for >1 mm were operated. Patients with recurrent pterygia and other eye diseases were excluded from the study. Cases with positive hepatitis markers and human immunodeficiency virus were also excluded from the study. All cases were handled by the same surgeon.

The patients were controlled at postoperative days 1, 3, 7, and 10, weeks 2 and 4, and then at monthly intervals. At control visits, the cornea and graft were biomicroscopically examined. The presence of recurrence and complications was recorded.

Preparation of T-PRF

Before preparation of the defect site for operation, blood samples drawn in one attempt using a 20 ml syringe were transferred equally at once into two Grade IV sterile titanium tubes. The tubes were reciprocally placed into the IntraSpin L-PRF centrifuge system and centrifuged at 2,700 rpm for 12 min at room temperature. PRF clot was removed from the tubes using sterile forceps (Figure 1). It was meticulously separated from the underlying layer of red blood cells. Buffy coat portions of PRFs were removed from serum using a PRF Box, and a homogenous membrane was obtained.

The membranes obtained were stabilized using a disc and were measured using digital calipers. The arithmetic mean of the measured values was calculated to estimate the mean thickness of the graft.

Surgical Technique

Local anesthesia was applied through a lidocaine injection containing 0.1–0.2 mL 2% epinephrine into the main body of the pterygium. Under an operating microscope, the pterygium was dissected at the level of the limbus using Westcott scissors. The pterygium tissue was separated from the cornea using a crescent knife. Residual tissues on the cornea were meticulously and completely cleansed. For all patients, a diamond-tipped burr was used to smooth out the cornea. The pterygium tissue separated from the cornea was removed using conjunctival scissors together with the underlying Tenon capsule. Bleeding foci (if any) were cauterized using bipolar wet field cautery. The prepared T-PRF was covered over the sclera not exceeding the limbus and was sutured to the conjunctiva with 8/0 polyglactin sutures (Figure 2).

Eyes of all patients were covered using eye bandages after surgery until the corneal epithelium healed. Postoperatively, the patients were given topical tobramycin (3.00 mg/mL), prednisolone sodium phosphate (1%), sodium hyaluronate as a lubricant (0.150 g/100 mL) four times a day, and carbomer (2 mg/1 g) at night before sleeping. Steroids were used for 8 weeks, and other drugs for 1 week. The sutures were removed at postoperative week 2.

RESULTS

Twelve eyes of total 12 patients (men, 5 and women, 7) were included in the study. The mean age of the patients was 52.1 ± 12.6 (30–75) years. The mean follow-up period of the patients was 2.91 ± 1.37 (1–5) months. The follow-up period of total 8 cases exceeded 3 months. Recurrence was observed in total 2 (16.6%) cases. Recurrences were observed in 1 case at month 4 and in another case with temporal pterygium at month 3 of the follow-up period.

The T-PRF membrane thickness was 0.81 ± 0.23 mm. The T-PRF membrane was resorbed at a mean period of 8.41 ± 1.37 days. In 3 cases, resorption of autograft was observed before completion of conjunctivalization. As a result of early resorption, development of the bare sclera was observed. In other cases, completion of conjunctival epithelization was seen. No complications were observed in any case (Figures 3, 4).

DISCUSSION

The main objective of all surgical techniques performed for pterygia was to eliminate the pterygium tissue and to relieve cosmetic and optic problems. Modifying classical techniques and the search for the development of techniques for these methods have prevented the development of recurrence, which is the greatest problem in the treatment of pterygium. Besides, trying to reconstruct tissue that yields the best cosmetic outcomes that cannot be achieved with classical methods has also been a part of this research.

In the literature, recurrence rates of up to 38%–88% have been reported for the bare sclera technique (19, 20). A scarce number of studies about simple conjunctival closure technique have been cited in literature, and recurrence rates ranging between 2% and 69% have been reported (21, 22). However, the safety of the conjunctival flap technique with lower recurrence rates has been indicated in literature (23). Reported recurrence rates ranged between 1% and 15% (24–26). In literature, the success rates of conjunctival autograft were reported between 5% and 30% (11, 27–36); however, for limbal conjunctival autograft technique, recurrence rates varying between 0% and 15% have been indicated (37–41).

Recurrence rates ranging from 4% to 60% have been reported with the use of an amniotic membrane, which has anti-inflam-

matory and antiangiogenic effects (42, 43) in pterygium surgery. The use of an amniotic membrane was reported to be more appropriate, particularly in patients with recurrent pterygium who also need glaucoma surgery (44). We believe that the amniotic membrane is an allograft, whereas T-PRF has the advantage of being an autograft. Therefore, T-PRF can replace the amniotic membrane in techniques wherein the use of an amniotic membrane is indicated. Further studies are needed to clarify this issue.

Mitomycin C (MMC) used to decrease recurrence in pterygium surgery also decreases tissue proliferation and fibroblastic activity. When MMC is used, recurrence rates change between 0% and 40% (11). The T-PRF membrane we used can be combined with similar additional treatments. In two patients with recurrent pterygium who were not included in our study, we applied T-PRF together with MMC without any subsequent complication, thereby assuring conjunctival epithelization. In cases with recurrent pterygium, MMC–T-PRF combination is being used in a separate study.

Titanium-platelet-rich fibrin (T-PRF) developed by Tunali et al. (16) was first tested in an animal model, and its effectiveness on the healing of connective tissue was investigated. T-PRF used in rabbits persisted at postoperative day 10. It was resorbed at postoperative day 15 and demonstrated a very good regenerative potential with bone calluses and newly formed connective tissue. In our study, early resorption was observed as a disadvantage. The natural characteristics of a teardrop may be the cause of early resorption in addition to the thickness of the membrane. Early resorption causes the formation of bare sclera. The bare sclera increases recurrence rates (19, 20). Revisions in surgical technique aiming to prolong resorption time of the autograft are thought to further decrease recurrence rates.

In recent studies, the correlation between angiogenic growth factors such as VEGF, basic fibroblast growth factor, TGF- β , and PDGF and formation, and recurrence of pterygium has been demonstrated (45–47). Some studies tended to demonstrate that limbal stem cell failure is the main impairment in the pathogenesis of pterygium (11).

L-PRF contains PDGF, TGF- β , insulin-like growth factor, VEGF, fibroblast-derived growth factor, and epidermal growth factor. Leukocytes trapped in the fibrin matrix secrete some inflammatory and wound healing cytokines (interleukin (IL)-1 β , IL-4, IL-6, and TNF- α) (48).

Maturation and healing of the soft tissue are realized via angiogenesis, immune control, utilization of the stem cells in circulation, and epithelial closure of the wound site. The effect of the fibrin matrix structure on angiogenesis may be explained by a three-dimensional fibrin gel structure and by the simultaneous activation of the cytokines it contains. Its main angiogenesis is realized by the action of fibroblast growth factor, VEGF, and PDGF, which are soluble factors in the fibrin gel (49).

In an animal study conducted in 2015, Tunali et al. (50) investigated the effect of T-PRF on bone healing and reported that new bone maturation rate as for new bone formation in the defects induced in rabbit calvaria is at its highest statistically significant level when compared with other groups. Besides, newly formed

bone retained its original form. This phenomenon suggested that L-PRF may be using tissue memory. Different studies are needed on this subject. We believed that by using T-PRF in pterygium surgery, conjunctivalization might terminate at the limbal border zone.

In conjunctivoplasty, T-PRF autografts provide adequate membranous closure in pterygium surgery. It may offer an advantage, particularly in filtration surgery by leaving the conjunctival space intact. In this surgery that is performed without impairing intact conjunctival tissue, a decrease was observed in the duration of surgery. This technique facilitates harvesting tissues nearby rather than at distant regions.

CONCLUSION

Our study is still ongoing. The increase in the number of cases will yield more clear-cut outcomes. We wanted to share our preliminary outcomes. Based on our early-phase outcomes, T-PRF can be used in pterygium surgery. Large-scale studies and development of the technique are needed to determine the effectiveness and reliability of this new technique.

Ethics Committee Approval: Ethics committee approval was received for this study from the Ethics Committee of Bezmialem Vakıf University School of Medicine.

Informed Consent: Written patient consent was obtained from patients participating in this study.

Peer-review: Externally peer-reviewed.
